From Assistance to Authority

Calibrating AI Influence for Professional Judgment, Capability Growth, and Independence

Xiangning(Shannon) Li

Starting Point: DealLens as a Working System and a Larger Research Question

AI can improve a professional decision in seconds. But after months of relying on it, is the professional better equipped to decide alone—or merely better at using AI? DealLens makes this question experimentally tangible. Built as an evidence-grounded decision-support system for B2B sales engineering, it connects Salesforce opportunities with Gong conversations, reconstructs evolving deal risk from Call 4 onward, and links predictions to inspectable evidence and revisable next-action guidance. Its predictive layer detects 82.5% of eventual losses at Call 4 and 93.2% at Call 8. Rather than treating these predictive results as the endpoint, this research uses the working system as a probe to study how AI enters judgment, gains authority, and changes independent capability. The underlying mechanisms span moment-level evidence evaluation, role-specific influence and responsibility, independent skill development, and capability-triggered support fading. These mechanisms may also be investigated beyond sales, including health-related decision support, counseling and support work, education, and other consequential human–AI settings.

Research gap and central question

From trust to professional judgment. Existing human–AI interaction research shows that appropriate reliance depends on task difficulty, AI performance, and users' confidence in their expertise [2–4, 7]. Explanations can support verification, but users also weigh their intuitions and the cognitive effort of evaluating AI advice [5, 6]. Yet an important question remains: how does AI enter and reshape human reasoning? Understanding when professionals accept, modify, reject, or interrogate AI advice across expertise, uncertainty, and disagreement requires examining decision processes rather than final outcomes alone.

From repeated assistance to epistemic authority.AI increasingly acts as an information source, challenger, advisor, or delegated assistant. Interface design shapes whether users perceive AI as a tool or collaborator [9], process-oriented support addresses limitations of recommendation-centric systems [8], and deliberative AI demonstrates benefits of structured human–AI disagreement [14]. However, how different AI roles shape epistemic authority over repeated interactions remains unclear: when AI judgments become authoritative, how verification and contestation evolve, and whether humans retain meaningful decision ownership. These dynamics distinguish productive collaboration from uncritical deference.

From immediate performance to lasting human capability.AI recommendations can improve immediate decisions without necessarily producing learning [1], while misconception-aware explanations can strengthen independent decision-making [12]. Research also emphasizes cognitive engagement [10], associations between GenAI confidence and critical-thinking effort [11], trade-offs in AI-supported reflection [13], and human capabilities beyond conventional performance metrics [15]. Yet whether sustained exposure to different AI roles develops transferable capability or dependence—and when assistance should fade—remains insufficiently understood. Addressing this gap requires connecting moment-level judgment, longitudinal authority formation, AI-off capability assessment, and adaptive scaffolding. It also requires distinguishing formal decision ownership from meaningful evidence evaluation: Study 2 examines role-sensitive responsibility boundaries, while Study 3 separately measures independent capability.

Central question: When does useful AI assistance become epistemic authority, and how can AI systems strengthen human judgment and capability while preserving contestability, decision ownership, and eventual independence?

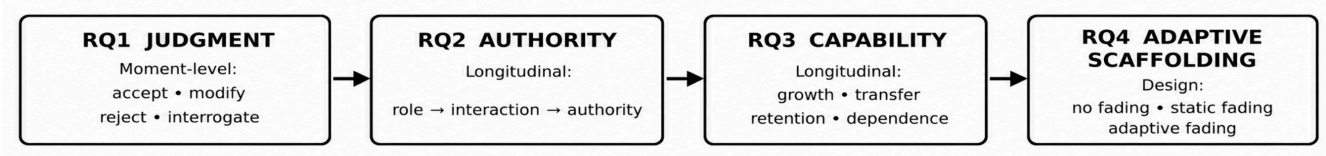

Figure 1. Progressive research framework linking moment-level judgment, role-shaped authority formation, independent capability development, and capability-triggered adaptive scaffolding across four interconnected studies.

Four research questions

RQ	Focus	Research question
1	Judgment	How does AI advice alter professional judgment across agreement, disagreement, uncertainty, and expertise?
2	Authority	How do different AI roles shape authority and interaction patterns over repeated use?
3	Capability	How do sustained interactions with different AI roles shape independent professional capabilities, and which gains transfer and persist when AI assistance is removed?
4	Adaptive scaffolding	Can capability-triggered adaptive fading improve independent judgment and transfer compared with fixed fading or continuous AI support?

Study 1 — Mapping the moment AI enters professional judgment

RQ1 — How does AI advice alter professional judgment across agreement, disagreement, uncertainty, and expertise?

Research purpose

Identify recurring interaction patterns at the moment AI enters professional reasoning, examining how expertise shapes the ways people verify, integrate, challenge, or reject AI advice. The study investigates not simply whether professionals follow AI recommendations, but when and why AI changes their reasoning and decision ownership. To capture this distinction, the unit of observation is a situated judgment episode linking the AI's contribution to what the professional understands, does, and can subsequently justify.

Participants and sample-size rationale

Target N=30 professionals across three experience groups (early-career, mid-career, senior; 10 per group). Experience is characterized by relevant practice, decision-making responsibility, and domain familiarity rather than job title alone. The three groups enable comparisons of how professional expertise shapes evidence verification, confidence calibration, and responses to AI–human disagreement. Ten participants per group provide repeated observations for identifying within-group patterns and contrasting mechanisms across experience levels, while remaining feasible for an exploratory qualitative study. Recruitment may extend within a group if substantively new patterns continue to emerge.

Procedure and data collection

Each participant completes a 60–75 minute session with briefing, four case-based think-aloud tasks, and a retrospective interview. De-identified cases vary in model confidence, decision stakes, risk trajectory, and outcome. For each case, participants first record an unaided judgment, intended action, confidence, and supporting evidence. After receiving AI guidance, they may inspect evidence, question recommendations, and revise their decisions. Synchronized interaction logs and recordings link each AI intervention to subsequent verification, clarification, decision changes, and final rationales. Video-assisted retrospective interviews revisit consequential moments to examine what participants understood, what contextual knowledge they considered, and why they accepted, modified, or rejected AI advice.

Evaluation

AI influence is evaluated through changes in risk judgments, intended actions, confidence calibration, and the quality of evidence-grounded reasoning. Behavioral indicators include verification of supporting and counter-evidence, clarification requests, contextual corrections, and justified acceptance or rejection of AI recommendations. Advice comprehension, expressed agreement, and actual decision incorporation are assessed separately, distinguishing informed reliance from uncritical compliance or apparent agreement without action. Comparisons across experience groups examine whether expertise affects uncertainty recognition, evidence scrutiny, perceived AI authority, and decision ownership. Video-assisted retrospective accounts help interpret ambiguous behaviors, particularly when participants accept advice without visible verification or reject otherwise accurate recommendations. The emphasis is on identifying meaningful differences in judgment processes rather than treating greater AI acceptance as inherently better or worse.

Analysis

Each decision episode is reconstructed as an Advice–Response–Action trajectory, identifying consequential moments when AI changes reasoning, evidence selection, or intended action. Two coding layers classify AI interventions (evidence presentation, uncertainty disclosure, challenge, recommendation) and human responses (verification, clarification, informed acceptance, rejection, contextual correction, or unexamined compliance). A structured codebook guides independent coding of a subset by two researchers, followed by discrepancy resolution and refinement. Cross-case matrices compare trajectories across expertise levels, task stakes, uncertainty, and initial AI–human agreement or disagreement. Thematic and negative-case analyses integrate interaction traces with retrospective explanations to identify recurring mechanisms, such as verification-driven reliance, authority-driven deference, or principled override. Descriptive frequencies characterize the prevalence of these patterns without implying population-level causal effects. The resulting behavioral taxonomy also identifies role-sensitive benefits and risks that inform Study 2's initial matrix.

Expected Contribution

An expertise-sensitive framework of how AI advice enters professional judgment, distinguishing informed reliance, productive contestation, and authority-driven deference. By linking observable interactions with retrospective accounts, the study identifies the conditions under which AI changes reasoning, evidence evaluation, and decision ownership. Its behavioral taxonomy and documented failure cases provide empirical inputs for Study 2's preliminary Role-Benefit-Risk-Responsibility Matrix, while leaving role-specific responsibilities and governance boundaries to subsequent expert review.

Study 2 — Comparing how AI roles become authority

RQ2 — How do different AI roles shape authority and interaction patterns over repeated use?

Research purpose

Investigate how repeated exposure to four distinct AI roles shapes epistemic authority, evidence verification, contestation, reliance, and decision ownership. Grounding their intended benefits, priority risks, and responsibility

boundaries in Study 1 findings and focused expert review, this study examines not only whether professionals increasingly consult AI, but how different forms of assistance alter their reasoning and willingness to challenge it over eight weeks. The goal is to distinguish evidence-grounded collaboration from uncritical deference, while identifying how different AI roles shape the emergence and boundaries of epistemic authority over time.

Participants and sample-size rationale

Target N=32 professionals in an 8-week deployment, randomly assigned to four stable AI roles (8 per role), with professional experience balanced where feasible. A between-subject design avoids contamination from switching roles during authority formation. Each participant contributes approximately two naturally occurring consequential decision episodes per week, yielding an expected 128 episodes per role across eight weeks. These repeated observations capture within-person behavioral changes rather than independent samples. The study emphasizes exploratory longitudinal mechanisms, with results informing future confirmatory research.

Procedure and data collection

Table 1. Provisional role–benefit–risk–responsibility matrix informed by Study 1, subject to expert review (N = 4–6) before deployment.

AI Role	Intended Benefit	Priority Risk	Responsibility
Evidence Provider	Inspectable evidence, uncertainty	Missing sources; selective omission	System: trace sources/coverage Professional: verify before acting
Challenger	Relevant counter-evidence, reflection	Spurious challenges; excess burden	System: proportionate challenge policy Professional: assess counterclaims
Advisor	Feasible evidence-based next actions	Unsupported advice; uncritical uptake	System: trace rationale Professional: evaluate rationale/feasibility
Delegate	Efficient authorized low-risk work	Overreach; non-reversible execution	System: enforce permissions/audit trail Professional: approve and review

Study 1 judgment episodes and interaction codes first inform a provisional Role-Benefit-Risk-Responsibility matrix (above). A focused review with 4–6 SE, SE managers, and system designers then challenges its boundaries, missing harms, accountable actors, and counterexamples; disagreements are documented, and the matrix is revised before deployment. The four roles are implemented on the same DealLens interface, model, and evidence sources through distinct system prompts, response policies, and tool permissions: Evidence Provider surfaces sources and uncertainty without action advice; Challenger tests assumptions and introduces relevant counter-evidence; Advisor recommends justified next actions without executing them; Delegate drafts or performs explicitly authorized, reversible low-risk actions. Pre-deployment test scenarios check permitted/prohibited behaviors and tool access; sampled output audits throughout the eight weeks check role fidelity and drift, separately recording boundary violations versus user reliance. Each of 32 participants uses one role for eight weeks; interaction logs track evidence inspection, revisions, overrides, and delegation, weekly surveys capture perceived authority and decision ownership, and Weeks 0/4/8 interviews probe consequential disagreements.

Evaluation

Shared outcomes: AI-first consultation, independent evidence-grounded justification, perceived authority, decision ownership, and appropriate reliance are measured consistently across roles. Role-specific benefit–risk checks examine evidence provenance and omission detection (Provider), relevant challenges and unnecessary burden (Challenger), recommendation traceability and action feasibility (Advisor), and authorization compliance, error oversight, and reversibility (Delegate). Role-recognition probes and sampled audits establish whether participants actually encountered the intended intervention, while common case characteristics help distinguish role effects from advice correctness, incompleteness, and task difficulty.

Analysis

Three linked analyses are used.

First, manipulation-check audits summarize role fidelity and boundary violations, distinguishing system drift from user behavior.

Second, exploratory longitudinal mixed-effects models and within-person trajectories compare shared authority indicators over eight weeks, accounting for repeated episodes and case characteristics; role × time contrasts remain tentative with eight independently assigned participants per role.

Third, Study 1 advice–response–action codes, interaction traces, and Weeks 0/4/8 interviews are triangulated to test role-specific mechanisms and benefit–risk trade-offs. Cross-case and negative-case comparisons examine unexpected authority shifts (e.g., over-reliance on an evidence-only system) and preserve disagreements over responsibility rather than forcing consensus.

Expected contribution

A comparative framework explaining how distinct AI roles shape the emergence and boundaries of epistemic authority. By contrasting evidence provision, reflective challenge, actionable advice, and bounded delegation, the study identifies role-specific pathways toward evidence-grounded reliance, productive contestation, and behavioral dependence. These

findings provide design principles for selecting appropriate forms of AI assistance and establish the interaction mechanisms examined for human capability development in Study 3.

Study 3 — Beyond AI-Assisted Performance: Measuring Independent Capability Growth

RQ3 — How do sustained interactions with different AI roles shape independent professional capabilities, and which gains transfer and persist when AI assistance is removed?

Research purpose

Investigate whether sustained AI assistance produces transferable growth in independent professional judgment or primarily improves performance while AI remains available. By comparing four AI roles, the study examines how different forms of assistance shape distinct capability trajectories, including growth, stagnation, dependence, and productive specialization. The distinction between successful AI-assisted work and what a professional can subsequently do without AI is the central outcome.

Participants and sample-size rationale

Study 3 reuses the N=32 participants from Study 2 (8 per AI role), linking capability development to their documented eight-week interaction histories. Each participant serves as their own baseline, with repeated AI-off assessments capturing longitudinal changes. The sample supports exploratory comparisons of role-specific development rather than definitive causal estimates; observed variation will inform future controlled studies.

Procedure and data collection

Participants complete an unaided baseline before deployment, followed by AI-off assessments at Weeks 2, 4, 6, and 8 using unseen, difficulty-matched DealLens cases. A delayed assessment at Week 12, four weeks after deployment, examines retention and transfer, with intervening AI exposure recorded. Each assessment requires independent risk judgment, critical-evidence identification, reasoning, next-action planning, and confidence reporting. Shared capabilities are evaluated consistently across roles, while role-specific patterns are examined qualitatively: Evidence Provider—evidence discrimination; Challenger—alternative-hypothesis generation; Advisor—strategy formulation; and Delegate—independent action planning and execution readiness. Study 2 interaction logs provide preceding histories of verification, challenge, modification, and delegation. To distinguish genuinely acquired skills from short-term task familiarity, cases are balanced on difficulty and decision stage but differ in customer context and surface cues; an independent panel defines critical evidence and acceptable alternative interpretations before scoring. No AI guidance is visible during assessment. Case order, assessment time, rationale revisions, and confidence judgments are recorded.

Evaluation

Independent capability is evaluated along five shared dimensions: (1) risk judgment quality, (2) critical-evidence identification and discrimination, (3) reasoning coherence and consideration of counterevidence, (4) next-action quality, and (5) confidence calibration. Two domain experts, blinded to role and time point, assess written judgments using anchored rubrics; major discrepancies are adjudicated by a third reviewer. Evidence identification can additionally be compared with a pre-annotated critical-cue set, while confidence is evaluated against judgment correctness. Role-specific outcomes test whether the distinct forms of AI assistance cultivate corresponding skills, without replacing common measures needed for cross-role comparison. Novel AI-off cases at each wave index transfer; Week 12 assesses retention after the eight-week deployment, not an assumption of complete AI abstinence.

Analysis

Exploratory mixed-effects growth models examine within-participant change across W0, W2, W4, W6, W8, and W12, including time, AI role, and role × time, with participant-level repeated measures and case difficulty accounted for. Figure 2 illustrates hypothetical role-specific capability trajectories, highlighting the contrasting patterns of growth, stagnation, and retention that this analysis aims to examine. Planned contrasts examine baseline-to-W8 improvement and W8-to-W12 retention; the five shared capability measures are compared across roles, while role-specific patterns are analyzed qualitatively. Estimates are reported with uncertainty intervals rather than overinterpreting small between-role groups. Interaction histories from Study 2 are aligned with later AI-off performance to explore whether verification, challenge, advice acceptance, or delegation precede capability gains or declines. Qualitative trajectory analysis of assessment rationales and selected interviews distinguishes transferable skill development, AI-dependent performance, productive specialization, and potential overreliance, while explicitly examining negative cases and missing observations. Because the study lacks a control group receiving no AI assistance during the eight-week deployment, findings are interpreted as exploratory associations between AI roles and capability trajectories rather than causal evidence of AI-induced learning or de-skilling.

Expected contribution

A longitudinal capability framework separating AI-supported performance from independent professional growth. Cross-role trajectories identify which reasoning skills improve, stagnate, or weaken under different forms of assistance, and whether any gains generalize to unseen cases and persist at Week 12. By linking interaction histories to unaided assessments, Study 3 yields pre-specified, observable capability signals—judgment quality, critical-cue detection, and confidence calibration—that directly inform the adaptive fading and restoration policy tested in Study 4.

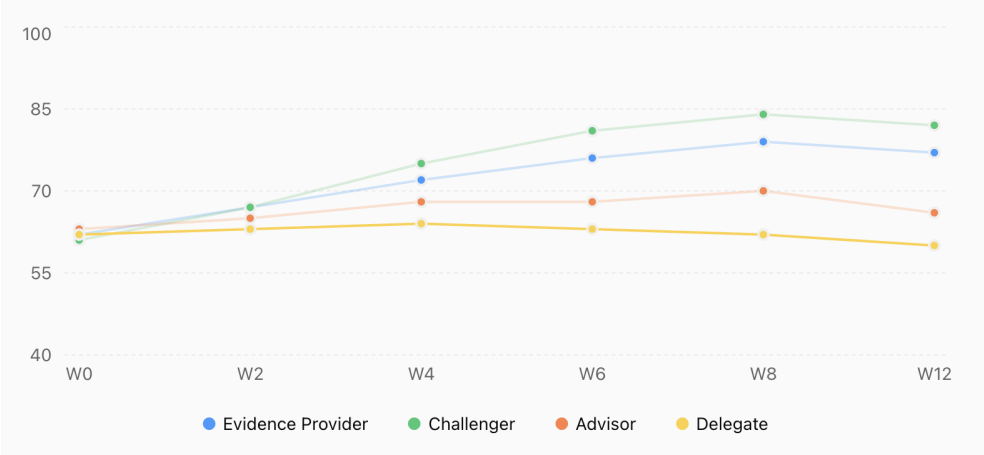

Figure 2. Illustrative independent capability trajectories across four AI roles (hypothetical data, not study results). W0–W8: deployment; W12: delayed AI-off assessment.

Study 4 — Designing and Evaluating Adaptive AI Scaffolding

RQ4 — Can capability-triggered adaptive fading improve independent judgment and transfer compared with fixed fading or continuous AI support?

Research purpose

Investigate when and how AI assistance should be reduced or restored as professional capability develops, and whether capability-triggered adaptive scaffolding can strengthen independent judgment without compromising task performance. Comparing three support policies—no fading, static fading, and adaptive fading—this study examines their effects on learning, transfer, retention, and reliance. The goal is to establish actionable design principles for AI systems that foster professional independence while providing support when needed.

Participants and sample-size rationale

Target N=30 professionals, randomly assigned to three scaffolding policies (10 per policy), with experience balanced where feasible. A between-subject design avoids carryover from previously experienced fading conditions. Six repeated training cases per participant provide approximately 60 decision episodes per policy. The study is an exploratory prototype evaluation intended to identify mechanisms, feasibility, and effect-size estimates for future confirmatory research.

Procedure and data collection

Participants complete an initial session of approximately 100–120 minutes: 10 minutes of briefing, a 10–15 minute unaided baseline, six matched DealLens training cases (8–10 minutes each), a 15–20 minute immediate AI-off transfer assessment using unseen cases, and 15–20 minutes of workload measures and retrospective interviews. A one-week delayed AI-off assessment (15–20 minutes) evaluates retention using additional unseen cases. All policies share the same interface, model, evidence sources, and three support levels: Full Support provides evidence and actionable guidance; Reduced Support requires initial human judgment and offers evidence with reflective prompts; Minimal Support provides evidence and uncertainty without direct recommendations. Three policies are compared: (1) No Fading maintains Full Support throughout; (2) Static Fading progresses through Full, Reduced, and Minimal Support across successive pairs of cases; and (3) Adaptive Fading changes levels after two consecutive cases meet pre-specified criteria for judgment quality, critical-cue detection, and confidence calibration, with support restored after substantial errors. Criteria are derived from Study 3 and calibrated before deployment. Interaction traces, support transitions, workload measures, and retrospective interviews are collected.

Evaluation

Primary outcomes are independent judgment quality and transfer on immediate and one-week delayed AI-off assessments, scored by blinded domain experts using standardized rubrics. Secondary measures include critical-evidence identification, confidence calibration, reasoning quality, training performance, workload, and perceived agency. Support exposure, time-to-fade, and reversions are recorded to distinguish policy effects from differences in assistance received.

Analysis

Exploratory longitudinal models compare capability changes and training trajectories across the three policies, accounting for repeated observations and case difficulty. Planned contrasts examine No Fading versus Static Fading to evaluate whether reducing support helps, and Static versus Adaptive Fading to assess the value of capability-contingent adjustment. Changes from baseline and delayed AI-off performance provide evidence of independent capability development. Transition-level analysis examines performance before and after fading or support restoration, while interviews and interaction traces explain premature fading, delayed fading, and individual differences. Results are interpreted as exploratory given the small group sizes and short intervention.

Expected contribution

An empirically grounded scaffolding framework specifying when AI should maintain, reduce, or restore support based on observable human capability. By comparing continuous, fixed, and adaptive assistance, the study identifies whether capability-triggered fading offers measurable benefits for independent judgment, transfer, and retention. The resulting design principles can inform AI systems that support professional development without unnecessarily sustaining dependence on automated guidance.

Research roadmap

The research progresses from observing influence to testing design interventions. Study 1 identifies expertise-sensitive moments when AI changes reasoning; these patterns inform which behaviors to track across roles. Study 2 uses Study 1 patterns to draft a provisional four-role benefit–risk–responsibility matrix, refines it with a focused expert review, verifies role fidelity, and tracks authority over eight weeks. Study 3 reuses that cohort to examine independent AI-off capability growth, transfer, and delayed retention, using shared and role-specific measures. Study 4 translates observable capability signals into pre-specified fading rules, comparing continuous, scheduled, and adaptive support. The sequence yields reusable artifacts: a judgment coding framework, expert-reviewed role-risk matrix with implementable policies and trace schema, AI-off capability rubrics, and an adaptive scaffolding prototype. All proposed comparisons remain exploratory given the sample sizes.

Study	Primary analytic object	Concrete output	Feeds into
1	AI influence point	Expertise-sensitive judgment and contestation pattern map	Behavioral coding scheme for longitudinal traces
2	Role-specific authority trajectory	Four interaction policies; authority and ownership trajectories	Documented exposure histories for Study 3
3	Independent capability trajectory	Shared and role-specific rubrics; AI-off growth, transfer, and retention profiles	Capability signals for Study 4 fading thresholds
4	Support transition policy	Fading thresholds, restoration rules, and prototype evaluation	Portable scaffolding design principles

Research Vision and Broader Impact

The central ambition of this research is to move beyond evaluating what AI helps people accomplish toward understanding what AI assistance leaves behind in human judgment. An effective AI system should not merely produce better decisions today; it should help people develop the expertise, confidence, and independence to make better decisions tomorrow. This requires understanding when assistance becomes epistemic authority, how different AI roles shape human reasoning, and when systems should deliberately reduce their influence.

From empirical understanding to actionable design principles: The four studies form a cumulative research agenda: identifying how AI advice enters professional judgment, explaining how role-specific assistance shapes authority and responsibility, measuring whether sustained interaction develops transferable independent capability, and testing when adaptive scaffolding should maintain, reduce, or restore support. Together, they aim to produce more than isolated empirical findings: a connected set of behavioral taxonomies, role-sensitive design frameworks, longitudinal capability measures, and experimentally evaluated scaffolding policies. These contributions would provide a foundation for designing AI systems that remain useful without making human judgment increasingly dependent on them.

From DealLens to broader human–AI interaction: DealLens offers a working research foundation rather than a hypothetical system, with longitudinal decision data, inspectable evidence, and an extensible interaction interface. Sales engineering provides the initial empirical setting, but the underlying questions extend to health-related decision support, psychosocial support, education, and other consequential settings where AI increasingly influences how people interpret evidence and exercise expertise. Generalization across these domains will require further empirical validation and context-specific safeguards. By building on an implemented system and a coherent sequence of testable studies, this agenda offers both an immediate path to research contribution and a longer-term direction for investigating human-centered AI.

Ultimately, the measure of successful human–AI collaboration should be not only how much AI can do for people, but how much more capable, independent, and empowered people become through working with it.
